Title:

Influence of aggregated particles on biodegradation activities for dimethylarsinic acid (DMA) in Lake Kahokugata

Running head:

Biodegradation of dimethylarsinic acid by aggregates

Abstract

Aquatic arsenic cycles mainly depend on microbial activities that change the arsenic chemical forms and influence human health and organism activities. The microbial aggregates degrading organic matter are significantly related to the turnover between inorganic arsenic and organoarsenic compounds. We investigated the effects of microbial aggregates on organoarsenic mineralization in Lake Kahokugata using lake water samples spiked with dimethylarsinic acid (DMA). The lake water samples converted 1 µmol L⁻¹ of DMA to inorganic arsenic for 28 days only under anaerobic and dark conditions in the presence of microbial activities. During the DMA mineralization process, organic aggregates >5.0 µm with bacterial colonization increased the densities. When the organic aggregates >5.0 µm were eliminated from the lake water samples using filters, the degradation activities were reduced. DMA in the lake water would be mineralized by the microbial aggregates under anaerobic and dark conditions. Moreover, DMA amendment enhanced the degradation activities in the lake water samples, which mineralized 50 µmol L⁻¹ of DMA. The DMA-amended aggregates >5.0 µm completely degraded 1 µmol L⁻¹ of DMA with a shorter incubation time of 7 days. The supplement of KNO₃ and NaHCO₃ to lake water samples also shortened the DMA degradation period. Presumably, the bacterial aggregates involved in the chemical heterotrophic process would contribute to the DMA-biodegradation process in Lake Kahokugata, which is induced by the DMA amendment.

Key words; arsenic cycle, organoarsenic compounds, biodegradation, aggregate
Introduction

The arsenic species in aquatic ecosystems changed their chemical forms mainly dependently on the microbial activities that metabolize the arsenic species, and some arsenic chemical forms are known to endanger human health and organism activities at high concentrations (Cullen and Reimer, 1989, Neumann et al., 2010). Among the variety of arsenic species, arsenate, arsenite, and methyl arsenic compounds dominate in both fresh water and seawater environments (Oremland and Stolz, 2003). Microorganisms, such as phytoplankton (microalgae) and bacteria, methylate arsenate into monomethylarsonic acid ($\text{CH}_3\text{AsO(OH)}_2$; MA(V)) and dimethylarsinic acid ($\text{(CH}_3)_2\text{AsO(OH)}$; DMA(V)) and subsequently convert the methyl arsenic compounds to more complex organoarsenic compounds, such as arsenobetain and arsenosugar (Howard and Comber, 1989). However, a significant positive correlation between the in situ amounts of chlorophyll a (the biomass of microalgae) and those of organoarsenic compounds has not been found, because the environmental degradation of organoarsenic compounds by bacteria had led to this inconsistency (Sohrin et al., 1997).

The dominant chemical forms of arsenic compounds in a number of lakes and estuaries have been reported to change seasonally by the degradation and production of organoarsenic compounds (Anderson and Bruland, 1991, Maki et al., 2009). A few reports have described that bacterial consortia in marine environments could degrade the amended organoarsenic compounds (Sanders, 1979, Kaise et al., 1985) and that bacterial population associated with crabs (Khokiattiwong et al., 2001) and mussels (Jenkins et al., 2003) also had the degradation activities for organoarsenic compounds.
The several species of bacterial isolates degrading organoarsenic compounds were obtained from activated sludge (Quinn and McMullan, 1995) and natural environments (Lehr et al., 2003, Maki et al., 2006). The degradation process of organoarsenic compounds is worthy of study for understanding the ecological dynamics and distribution of arsenic compounds in aquatic environments.

In aquatic environments, organic aggregates colonized by heterotrophic microorganisms are important components in the turnover of both organic and inorganic matter (Grossart and Ploug, 2000). The bacteria population attached to organic aggregates has been reported to exhibit higher metabolic activities than free-living bacterial population in the surrounding waters (Caron et al., 1982, Ghiglione et al., 2007). Organic aggregates and their surrounding environments are the hot spots of the microbial process, during which the degradation activities of organic matter are expanded (Crump et al., 1999). In the organic aggregates where concentration gradients of oxygen develop, the organic-degradation activities of anaerobic bacteria, such as denitrifying bacteria and methane-synthetic bacteria, are high (e.g. Oremland 1979).

Our previous study demonstrated that the DMA biodegradation in lake water was activated only under anaerobic and dark condition, indicating the possibility that the organic aggregates provide the hot spots for the DMA-degrading microorganisms and support the DMA-biodegradation (Maki et al. 2009). However, the actual biodegradation of DMA by organic aggregates with bacterial colonization is still unknown.

In this study, the influence of aggregates on the DMA-biodegradation process were estimated in detail using lake water samples that had been collected from a single
lake, Lake Kahokugata, and spiked with DMA. We also compared the DMA-degradation activities between DMA-amended and unamended lake water to evaluate the activation of DMA degradation by the amendment. The microbial consortia amended with some chemical substrates were reported to elevate the biodegradation for the chemical substrates (e.g. Eilers et al. 2000). Moreover, for elucidating the metabolic characteristics of bacterial consortia relating with DMA degradation, the chemical substrates that activate the anaerobic bacteria, such as denitrifying bacteria and methane-synthetic bacteria, were added to lake water samples and the induction of DMA-biodegradation activities was evaluated. DMA was selected as a representative organoarsenic compound that is widely distributed in freshwater (Sohrin et al., 1997).

Materials and Methods

Sampling at Lake Kahokugata

A water sample at the depth of 1 m was collected in polycarbonate bottles from Lake Kahokugata in Ishikawa Prefecture, Japan. Lake Kahokugata is eutrophic and has experienced wastewater inflow from cities and croplands. Lake Kahokugata is shallow with a depth of less than 2 m and the water was frequently mixed throughout the four seasons. The oxygen levels in the lake water sample ranged from 2.0 mg L\(^{-1}\) to 8.3 mg L\(^{-1}\) during the investigation period. When the water transparency was measured using a standard 25 cm black and white Secchi disk, the disk depth was approximately 1.0 m from the water surface at the sampling dates, indicating that the sun irradiation hardly reached a depth below 1 m. After at least 2 hours of sampling, the surface water samples
of Lake Kahokugata in polycarbonate bottles were used for several culture experiments, in which we estimated the DMA-biodegradation activities of lake water under several experimental treatments and the microbial dynamics during the DMA-degradation process. The concentrations of inorganic arsenic and organoarsenic compounds in the lake water without the addition of DMA were stable below 20 nmol L\(^{-1}\) during the entire experiment.

**Influences of the microbial activities on DMA biodegradation in lake water**

Lake water samples collected in polycarbonate bottles from Lake Kahokugata on 29 August 2008 were used to investigate the DMA-biodegradation activities in lake water samples incubated under anaerobic and dark conditions. Fifteen polycarbonate bottles (500 mL) were filled up with lake water and transferred to our laboratory. Within 2 hours of sampling, 500 µL of a 1 mmol L\(^{-1}\) DMA (Nacalai Tesque, Kyoto, Japan) solution was added into 3 bottles, and the final concentration of DMA was adjusted to 1 µmol L\(^{-1}\). The bottles were incubated under anaerobic and dark conditions. To produce the anaerobic conditions, the air phases in the bottles were kept at the lowest possible level, and the lake water samples were purged with nitrogen (100 mL min\(^{-1}\)) for 0.5 hours. The bottles were incubated in a temperature-controlled room (20 °C) under dark conditions by covering the bottles with aluminum foil. The anaerobic and dark condition of incubation was optimal for DMA-degradation in lake water (Maki et al., 2009).

The remaining 12 bottles were used for the experiment that the microbial activities in the lake water samples were eliminated using four treatments: the lake
water sample was autoclaved at 120 °C for 20 minutes; an antibiotic mixture was added to each sample of lake water at a final concentration of 10 mg L⁻¹; sodium azide was added to each sample of lake water at a final concentration of 10 mg L⁻¹; and the lake water was filtrated through a 0.02 µm pore-size filter polycarbonate filter (Whatman, Tokyo, Japan). Each treatment was performed using triplicate bottles. The bottles of the lake water samples treated by each method and spiked with 1 µmol L⁻¹ DMA were incubated at 20 °C under anaerobic and dark conditions.

At 0, 14, 21, 28 and 56 days of the incubation, portions (10 mL) of the lake water samples were collected, and the concentrations of arsenic species were determined using a cold-trap hydride-generation atomic-absorption (HG-AA) speciation procedure. After sampling of subsamples, the air space volumes in the bottles were exchanged by nitrogen.

**Effects of aggregate sizes in lake water on DMA biodegradation**

The lake water samples, which were collected from Lake Kahokugata on 22 May 2008, were filtrated through polycarbonate filters with four pore sizes of 10, 5.0, 1.2, and 0.22 µm (Millipore, Tokyo, Japan). Within 2 hours of sampling, each filtrate was placed in polycarbonate bottles (500 mL) and spiked with DMA added at a final concentration of 1 µmol L⁻¹. Triplicate bottles were prepared for each sample of filtrate, and incubated at a temperature of 20 °C under anaerobic and dark conditions as described. At every 7 or 14 days of the incubation period (56 days), portions (10 mL) of the lake water samples were collected to measure the concentrations of arsenic species.
Induction of DMA biodegradation in the DMA-amended lake water samples

For investigating the activation of DMA degradation by the DMA amendment, the lake water samples collected on 22 May 2008 were spiked with 1 µmol L\(^{-1}\) of DMA and amended at 20 °C under anaerobic and dark conditions for 28 days (DMA-amended lake water sample). DMA in the DMA-amended lake water samples was completely converted to inorganic arsenic within 28 days of incubation. The 500 mL DMA-amended lake water samples were sequentially filtrated through a series of polycarbonate filters with pore sizes of 5.0 and 1.2 µm (Millipore, Tokyo, Japan). The aggregates on the 5.0 and 1.2 µm filters were added to 500 mL lake water samples that were collected on 9 June 2008 and filtrated through a 0.02 µm pore-size polycarbonate filter. The filtrate with the 1.2 µm filters was also used for the following experiments as the lake water sample including <1.2 µm aggregates. Finally, the lake water samples including the aggregates separated into three fractions: > 5.0 µm, 5.0 µm to 1.2 µm, and <1.2 µm were prepared. One µmol L\(^{-1}\) of DMA was spiked to the lake water samples including each fraction of aggregates and unfiltrated DMA-amended lake water sample (500 mL). The water samples were incubated at 20 °C under anaerobic and dark conditions. At every several days of incubation, the concentrations of arsenic species in portions (10 mL) of the lake water samples were measured.

Next, to evaluate the concentration capacities of DMA-degradation in DMA-amended lake water, 5 polycarbonate bottles (500 mL) were filled up with lake water collected from Lake Kahokugata on 22 May 2008. Four bottles were amended with 1 µmol L\(^{-1}\) of DMA for 28 days (DMA-amended lake water sample), and the other bottle was incubated without DMA amendment for 28 days (unamended lake water sample).
sample). The 4 bottles of DMA-amended lake water samples were then spiked with DMA at the final concentrations of 1, 5, 10, and 50 µmol L⁻¹, and the bottle of unamended lake water samples was also spiked with 10 µmol L⁻¹ DMA. These bottles were continuously incubated at 20 ºC under anaerobic and dark conditions. At every 7 days after the second DMA spike, portions (10 mL) of the lake water samples were collected to determine the concentrations of arsenic species.

Effects of chemical substrates on DMA biodegradation in lake water

The polycarbonate bottles (500 mL) were filled up with lake water samples collected from Lake Kahokugata on 11 September 2009. The lake water samples were supplemented with one of 10 kinds of chemical substrates; NaHCO₃ (final concentration: 1.0, 4.0, and 10 g L⁻¹), KNO₃ (1.0, 4.0, and 10 g L⁻¹), Na₂SO₄ (4.0 g L⁻¹), MgSO₄ (4.0 g L⁻¹), CuSO₄•5H₂O (4.0 g L⁻¹), FeSO₄•7H₂O (4.0 g L⁻¹), CH₃COONa (4.0 g L⁻¹), L-glucone (1.0 g L⁻¹), yeast extract (1.0 g L⁻¹), or L-cystin (1.0 g L⁻¹) (Nacalai Tesque, Kyoto, Japan). The amendment using NaHCO₃ and KNO₃ increase the activities of methan-synthetic and nitrogen-reducing bacterial consortia in lake water samples. The addition of Na₂SO₄, MgSO₄, CuSO₄•5H₂O, and FeSO₄•7H₂O activate the sulfate-reducing bacterial consortia. The addition of CH₃COONa, L-glucone, yeast extract, and L-cystin increase the cometabolic activities of several bacterial communities. Lake water samples without chemical-substrate addition were also prepared as controls. DMA was added to the lake water samples at a final concentration of 1 µmol L⁻¹, and each experiment was performed using triplicate bottles. After 21 days of incubation at 20 ºC under anaerobic and dark conditions, the concentrations of
arsenic species in the lake water samples were determined.

Measurements of the arsenic compound concentration

The cold-trap HG-AA speciation procedure was employed as the protocol previously reported (Braman and Foreback, 1973). The water subsamples were filtrated through a 0.45 µm cellulose ester filter (Millipore, Tokyo, Japan) and acidified and reacted with 10% w/v sodium tetrahydroborate. The produced arsines were swept by a flow of nitrogen into a cold-trap column cooled by liquid nitrogen. After the column was gently warmed by electrical heating, the arsines released from the column were loaded into a quartz-T tube held at ca. 900 °C in a flame in order to inorganic arsenic (arsenate), MMA and DMA, and quantified using an atomic absorption spectrometer Z-8100 (Hitachi, Chiba, Japan). In this experiment, the accuracy of the measured values was considered as 10 nmol L⁻¹.

Observation of particles in lake water samples using epifluorescence microscopy

The 500 mL lake water samples collected in 3 polycarbonate bottles from Lake Kahokugata on 22 May 2008 were spiked with DMA at a final concentration of 1 µmol L⁻¹. For 56 days of incubation at 20 °C under anaerobic and dark conditions, a 1-mL water subsample was collected from each bottle every week. The water subsamples were fixed with a glutaraldehyde solution at a final concentration of 1%. The samples were stained with DAPI (4',6-diamino-2-phenylindole) at a final concentration of 0.5 µg mL⁻¹ for 15 min and filtrated through a 0.22 µm pore-size polycarbonate filter (Millipore, Tokyo, Japan) stained with Sudan Black (Russell et al., 1974). After the
filter was placed on a slide on top of a drop of low-fluorescence immersion oil, a drop of oil was added and then covered with a cover slide. Slides were examined using an epifluorescence microscope (Olympus, Tokyo, Japan) under UV excitation. Under the microscopic observation, the free-living bacterial particles in lake water samples were observed as coccoid-like or bacillus-like particles with white-blue fluorescence with a diameter of below 1.0 µm. Furthermore, the particles with yellow fluorescence ranging from 1.0 µm to about 500 µm diameters were also observed. Among the yellow fluorescing particles, some of them were colonized with bacterial particles, and the others were not attached with the bacterial particles. A filter transect was scanned and the particles on the filter transect, which could be discriminated into free-living bacterial particles, yellow fluorescing particles without bacterial-particle attachment, and yellow fluorescing particles with bacterial colonization in two size categories (<5.0 µm and >5.0 µm), were enumerated. Each particle count was performed on 10 microscopic fields randomly selected.

Results

Influence of the microbial activities on DMA biodegradation in lake water

When the lake water samples were spiked with DMA at a final concentration of approximately 1 µmol L\(^{-1}\) and incubated at 20 °C under anaerobic and dark conditions, the concentration of DMA at the onset of the experiment decreased from 916 nmol L\(^{-1}\) (average) to the detection limit (avg.) during the first 28 days of incubation (Table 1). In accordance with the decrease of DMA, the concentration of inorganic arsenic, which
is considered to be the resultant product from DMA degradation, increased to 912 nmol L\(^{-1}\) at the 28th day and fluctuated the concentration of 900 nmol L\(^{-1}\) until 56 days of incubation. In contrast, when the microbial activities in the lake water samples were eliminated, the concentrations of DMA maintained for 56 days of incubation (Table 1). In the lake water samples that microbial activities were removed, no significant difference among incubation days were determined by the analysis of one-way ANOVA test. These results indicated that this DMA degradation occurred as a result of a biotic (microbiological) process under anaerobic and dark conditions.

Effects of aggregate size in lake water on DMA biodegradation

In this lake water samples spiked with DMA, the yellow fluorescing particles without bacterial particles decreased the densities from 3.2 x 10\(^4\) to 7.2 x 10\(^3\) particles mL\(^{-1}\) during the first 14 days of incubation and maintained low densities until 56 days (Fig. 1). The densities of yellow fluorescing particles <5.0 µm with bacterial colonization rapidly increased from 6.4 x 10\(^3\) to 3.3 x 10\(^4\) particles mL\(^{-1}\) during the first 7 days and decreased to 7.2 x 10\(^3\) particles mL\(^{-1}\) on the 21st day, maintaining the order of 10\(^3\) particles mL\(^{-1}\) until the 56th day. The densities of yellow fluorescing particles >5.0 µm with bacterial colonization gradually increased from 1.5 x 10\(^3\) to 2.9 x 10\(^4\) particles mL\(^{-1}\) for 28 days, and fluctuated over densities of 1.6 x 10\(^4\) particles mL\(^{-1}\) until the 56th day. The free-living bacterial cells maintained concentrations ranging from 10\(^4\) to 10\(^5\) cells mL\(^{-1}\) during the experimental period. The total densities of bacterial particles colonized on yellow fluorescing particles >5.0 µm were ranged from 2.0 x 10\(^4\) to 3.2 x 10\(^5\) particles mL\(^{-1}\) for 28 days (data not shown), suggesting that the total biomasses of
free-living and aggregate bacteria in the lake water were mostly equal at order levels.

When the filtrated and unfiltrated lake water samples were spiked with approximately 1 \( \mu \text{mol L}^{-1} \) of DMA, the lake water samples filtrated through a 10 \( \mu \text{m} \) pore-size filter degraded 90% of DMA and accumulated inorganic arsenic at a concentration of 860 nmol L\(^{-1}\) within 28 days, indicating a similar rate of DMA degradation to the unfiltrated lake water samples (Fig. 2a, b). In contrast, DMA spiked to filtrate samples through 5.0 \( \mu \text{m} \) and 1.2 \( \mu \text{m} \) pore-size filters significantly mineralized DMA for longer incubation times (42 to more than 56 days, respectively) (Fig. 2c, d), suggesting that the DMA-degradation activities decreased in the lake water samples filtrated through pore-size filters of less than 5.0 \( \mu \text{m} \). In the lake water samples filtrated through the 0.22 \( \mu \text{m} \) pore-size filter that could eliminate bacterial cells, DMA degradation was diminished (Fig. 2e).

**Induction of DMA biodegradation in the DMA-amended lake water samples**

After the lake water samples were incubated for 28 days with DMA, DMA was added to the DMA-amended lake water samples at a concentration of 1 \( \mu \text{mol L}^{-1} \) again. The DMA spiked into the DMA-amended lake water samples decreased rapidly, and the inorganic arsenic increased the concentrations from 964 to 1715 nmol L\(^{-1}\) within 7 days from the second spiked time of DMA (Table 2). In the unamended lake water sample, DMA spiked was converted to inorganic arsenic for long incubation times of 21 days from the second spiked time of DMA. When several sizes of aggregates collected from the DMA-amended lake water samples were added to the lake water samples filtrated through a 0.02 \( \mu \text{m} \) filter, the 1 \( \mu \text{mol L}^{-1} \) of DMA in the samples including aggregates...
>5.0 µm was completely converted to inorganic arsenic in 7 days (Table 2). The lake water samples including aggregates 1.2-5.0 µm or <1.2 µm completely mineralized the DMA for longer incubation times of 21 days and 28 days, respectively (Table 2). Consequently, aggregates >5.0 µm in the DMA-amended lake water samples kept the high activities of DMA biodegradation in lake water.

Furthermore, when the DMA-amended lake water samples were spiked with DMA at four concentrations of 1, 5, 10, and 50 µmol L⁻¹, the DMA was completely degraded within 7, 14, 28, and 200 days of incubation, respectively (Fig. 3a, b, c, d). In the unamended lake water samples including 10 µmol L⁻¹ of DMA, up to 4 µmol L⁻¹ of DMA could be degraded to inorganic arsenic for 56 days, and the DMA degradation ceased on the 200th day (Fig. 3e). These results mean that the DMA-amended lake water samples possessed higher activities of DMA degradation than the unamended lake water samples.

**Effects of chemical substrates on DMA biodegradation in lake water**

When the 10 kinds of chemical substrates were added to lake water samples spiked with DMA, only the lake water samples including KNO₃ and NaHCO₃ significantly mineralized 1 µmol L⁻¹ of DMA on the 21st day of incubation (Table 3). In the lake water samples supplemented with 4.0 g L⁻¹ of KNO₃ and NaHCO₃, DMA was remarkably decreased, and inorganic arsenic increased to over 900 nmol L⁻¹ on the 21st day of incubation. The lake water samples including 4.0 g L⁻¹ of KNO₃ and NaHCO₃ were different as compared the lake water samples without chemical-substrate addition and including the other 8 chemical substrates at the P<0.01 (One-way ANOVA test).
contrast, the lake water samples with 1.0 and 10 g L\textsuperscript{-1} KNO\textsubscript{3} and NaHCO\textsubscript{3} showed the wide range of DMA-degradation rates ranging from 25 % to 100 % on the 21st day. These results suggested that the addition of KNO\textsubscript{3} and NaHCO\textsubscript{3} at proper concentrations, such as 4.0 g L\textsuperscript{-1}, enhanced the initiation of DMA degradation in the lake water samples. During the experimental period of each chemical supplement, the pH in lake water samples ranged from 7.5 to 8.0, suggesting that the effects of pH on the degradation could be neglected (data not shown).

Discussion

Some microalgae in lake water and coastal seawater incorporate and accumulate inorganic arsenics instead of phosphorus and synthesize methyl-arsenic compounds for detoxification (Andreae, 1979, Hasegawa et al., 2001). However, a positive correlation between the \textit{in situ} amounts of microalgal biomass and methyl-arsenic compounds was hardly observed in aquatic environments, and the mineralization of methyl-arsenic compounds is considered to be responsible for cause this inconsistency (Anderson and Bruland, 1991, Sohrin et al., 1997). Sanders (1979) demonstrated that natural freshwater samples with DMA amendment exhibited DMA-degradation activities. Although organoarsenic compound in the terrestrial environments are volatilized as well as were mineralized to inorganic arsenic, the rates of DMA degradation was much greater than those of arsenic evolution from the terrestrial environments to atmosphere (Gao and Burau, 1997). In this study, when DMA was spiked into natural lake water samples collected from Lake Kahokugata, the concentration of inorganic arsenic increased in
accordance with the decrease of DMA under anaerobic and dark conditions (Table 1).  
The increase concentrations of inorganic arsenic after DMA disappearance were equal  
approximately to the decrease concentrations of DMA. Therefore, the more than 95 %  
of DMA spiked to the lake water samples would be degraded and converted to inorganic  
asenic. Furthermore, when microbial activities were eliminated from the lake water  
samples, the degradation of DMA and the accumulation of inorganic arsenic diminished  
(Table 1). In estuaries, biological demethylation has been reported to be the dominant  
process for the generation of inorganic arsenic from organoarsenic compounds  
(Anderson and Bruland, 1991). In Lake Kahokugata, DMA degradation is thought to  
constantly occur as a result of a biotic (microbiological) process.  
The epifluorescence microscopy observation using the DAPI staining technique  
revealed that the number of yellow fluorescing particles >5.0 µm with bacterial  
colonization increased during the DMA-degradation process (Fig. 1). Moreover, the  
lake water samples filtrated through >5.0 µm pore-size filters showed similar rates of  
DMA biodegradation to unfiltrated lake water samples, while the lake water samples  
filtrated through <5.0 µm pore-size polycarbonate filters completely degraded DMA for  
longer incubation times (more than 42 days) (Fig. 2). The bacteria-attached aggregates,  
which are stained with DAPI as yellow fluorescing particles, have important  
implications for DMA biodegradation in lake water. DAPI yellow fluorescing particles  
have been demonstrated to resemble detritus originated from planktonic materials on  
copepod fecal pellets (Mostajir et al., 1995). Some microorganisms in lake water and  
coastal seawater, such as fungi, bacteria, and phytoplankton, are known to accumulate  
inorganic arsenics and produce organoarsenic compounds (Andreae, 1979, Hasegawa et
al., 2001). Therefore, in natural environments, the microbial communities on/within the organic aggregates are thought to degrade the organoarsenic compounds, such as DMA, which are synthesized by microorganisms and included in the aggregates.

During the 28 days of the DMA-biodegradation period, the number of DAPI yellow fluorescing particles >5.0 µm with bacterial colonization increased (Fig. 1), suggesting that the bacteria form their colonies on organic aggregates >5.0 µm during the incubation period. Furthermore, the aggregates >5.0 µm obtained from the DMA-amended lake water samples also showed higher rates of DMA degradation than those of the unamended lake water samples (Table 2). Since the total cell densities of free-living bacteria and aggregate bacteria were mostly equal, the aggregate bacterial cells would have higher degradation activities than the free-living bacteria cells. The microbial degradation rates of organic matter on aggregates have been reported to be much higher than those estimated by the biomass production of aggregates (Ghiglione et al., 2007). Several studies found that the bacteria associated with aggregates exhibit significantly higher potential ectoenzymatic hydrolysis rates per bacterial cell, implying that organic matter is hydrolyzed faster on aggregates than in the surrounding water (Unanue et al., 1998). The formation of microbial colonies associated with the aggregates >5.0 µm would be an essential for the initiation of DMA degradation in lake water.

In the DMA-amended lake water samples and the lake water samples containing DMA-amended aggregates >5.0 µm, 1 µmol L⁻¹ DMA was rapidly converted to inorganic arsenic in 7 days (Table 2). On the contrary, DMA in the unamended lake water sample was completely degraded for longer incubation times of 21 days.
Furthermore, the DMA-amended lake water samples completely mineralized at least 50 \( \mu \text{mol L}^{-1} \) of DMA, whereas the unamended lake water sample could mineralize a maximum of 4 \( \mu \text{mol L}^{-1} \) of DMA (Fig. 3). These results suggested that DMA amendment activated the DMA-biodegradation activities of organic aggregates in the lake water. Bacteria attached onto 5- to 14-day-old aggregates exhibited higher respiration rates than those attached onto <5-day-old aggregates (Grossart and Ploug, 2000). In addition, enrichment of the microorganisms with organic compounds has been reported to influence the microbial species compositions and their metabolic activities (Eilers et al., 2000). When the aggregates were formed in the aquatic environments, a change in bacterial production and respiration occurred with a concurrent change in the bacterial community structure (Grossart and Ploug, 2000). Therefore, DMA amendment to lake water samples seems to activate the DMA-degrading bacteria and/or increase the microbial biomass on the aggregates, promoting the DMA-biodegradation activities.

Among all 10 kinds of chemical substrates supplemented to the lake water samples including DMA, the lake water samples including KNO\(_3\) and NaHCO\(_3\) at concentrations of 4.0 g L\(^{-1}\) completely degraded DMA for 21 days of incubation, while the lake water samples including the other 8 kinds of chemical substrates indicated no significant rates of DMA degradation on the 21st day (Table 3). The anaerobic reduction of nitrate, such as KNO\(_3\), to dinitrogen by nitrate-reducing bacteria was coupled to the oxidation of organic matter (Zumft, 1997). Furthermore, denitrifying bacteria formed nitrogen through anaerobic oxidation of ammonium coupled to nitrate reduction, suggesting that nitrate would promote the growth of denitrifying bacteria (Kniemeyer et al. 1999). The denitrification activities, which occurred in the organic aggregates, might
be induced by KNO₃ amendment and contribute to the DMA-degradation process. On the other hand, under anaerobic conditions in aquatic environments, NaHCO₃ and hydrogen were converted to methane by methane-synthetic bacteria, whereas the elimination of hydrogen induced the degradation of complex organic matter (McInerney et al., 1979). Zehnder reported that methane-synthetic bacteria would remove the methyl-group from methane compounds and reoxidize methane to carbon dioxide, which is involved in the anaerobic methane oxidization process of the natural environment (Zehnder and Brock, 1979). Probably, anaerobic microbial reactions relating to the methyl-transport and nitrate-reduction processes on organic aggregates are expected to be optimal for converting DMA to inorganic arsenic. Furthermore, the nitrogen and methane cycling on organic aggregates is expected to influence the organoarsenic-compounds mineralization that are key process for understanding the arsenic cycles in aquatic environments.

Figure legends

Fig. 1 Changes in the numbers of free-living bacterial cells (closed circles), yellow fluorescing particles without bacterial particles (open circles), yellow fluorescing particles <5.0 µm with bacterial colonization (open triangles), and yellow fluorescing particles >5.0 µm with bacterial colonization particles (open squares) in lake water samples to which 1 µmol L\(^{-1}\) of DMA was added. These particles were counted using epifluorescence microscopic observation with the DAPI staining technique. Each particle count was performed using triplicate bottles.

Fig. 2 Changes in the concentrations of arsenic compounds in lake water samples with or without filtration to which 1 µmol L\(^{-1}\) of DMA was added. Lake water samples without filtration (a) and those filtrated through polycarbonate filters with pore sizes of 10 µm (b), 5.0 µm (c), 1.2 µm (d), and 0.22 µm (e) were used. The lake water samples were incubated at 20 ºC under anaerobic and dark conditions. Open circles, closed circles, and closed triangles indicate the abundance of inorganic arsenic, DMA, and MMA, respectively. Each experiment was performed using triplicate bottles.

Fig. 3 Changes in the concentrations of arsenic compounds in DMA-amended lake water samples to which DMA was added at several concentrations of 1 µmol L\(^{-1}\) (a), 5 µmol L\(^{-1}\) (b), 10 µmol L\(^{-1}\) (c), and 50 µmol L\(^{-1}\) (d) after 28 days of amendment with 1 µmol L\(^{-1}\) of DMA and in unamended lake water samples to which DMA was added at a concentration of 10 µmol L\(^{-1}\) (e). The lake water samples were incubated at 20 ºC under
anaerobic and dark conditions. Open circles, closed circles, and closed triangles indicate
the abundance of inorganic arsenic, DMA, and MMA, respectively. Each experiment
was performed in triplicate. The concentrations of inorganic arsenic on day 0 were
initialized to 0 µmol L$^{-1}$ by eliminating amounts of inorganic arsenic carried by the first
DMA-amendment treatment.

*1 All values are given in nmol L⁻¹ and the standard error of the mean for triplicate bottles. The lake water samples spiked with DMA were incubated under anaerobic and dark condition at 20 °C for 21 days.

*2 Lake water was autoclaved at 120 °C for 20 minutes.

*3 Antibiotics mixture was added to lake water at a each final concentration of 10 mg L⁻¹.

*4 NaN3 was added to lake water at a final concentration of 10 mg L⁻¹.

*5 Lake water was filtrated with 0.02 µm polycarbonate filter.
